Task (d): results sheet and plain-language guide

Backtest with costs and an ESG floor. For the memo and the slides (Laurin). Written 3 November 2026 from the executed notebook. Group_8.

1. The result in four sentences

Each 1 July we ranked firms on the forecast of the model selected in task (b) (linear regression, refitted every year on earlier years only), held the top decile for twelve months and charged 20 basis points per unit of one-way turnover, on the full panel including firms that left (formation years 2018 to 2024, 84 months). The rule earned **9.4% a year against 8.8%** for the equal-weight benchmark (Sharpe ratio 0.46 against 0.42). Restricting the pool to firms with an Environmental score at or above the 50th and the 80th percentile gave 9.6% and 11.4%: **in this sample the floor did not cost return**, it cost concentration (about 19 names at the 80th percentile) and trading. The best rule's Sharpe advantage over the benchmark (+0.11) is **not distinguishable from noise** (95% interval -0.16 to +0.38).

2. The table (July 2018 to June 2025, after costs, full panel including firms that left)

Rule	Return (% a year)	Volatility (% a year)	Sharpe ratio	One-way turnover	Names held
Linear regression, no floor	9.39	16.80	0.457	0.70	94
Linear regression, floor 50th percentile	9.59	17.08	0.464	0.76	47
Linear regression, floor 80th percentile	**11.39**	18.38	**0.533**	0.82	19
Equal-weight benchmark (all firms)	**8.77**	17.12	**0.419**	0.17 (no cost)	945

Cost convention (from the starter): the replaced share of the portfolio is sold and bought, 20 bp each way, so 40 bp on the replaced share, charged in the first month of each holding year. Cost drag per year: 0.28 points (no floor), 0.31 (50th), 0.33 (80th). The benchmark is charged no cost, as in the starter. Floors: Environmental score at or above the 50th or 80th percentile of that formation year; the top decile is 10% of the restricted pool.

Sharpe difference to the benchmark (95% interval, 5,000 resamples of the 84 months)	Difference	Lower	Upper
No floor minus benchmark	+0.038	-0.159	+0.226
Floor 50th minus benchmark	+0.045	-0.176	+0.255
Floor 80th minus benchmark (best rule)	**+0.114**	**-0.162**	**+0.381**

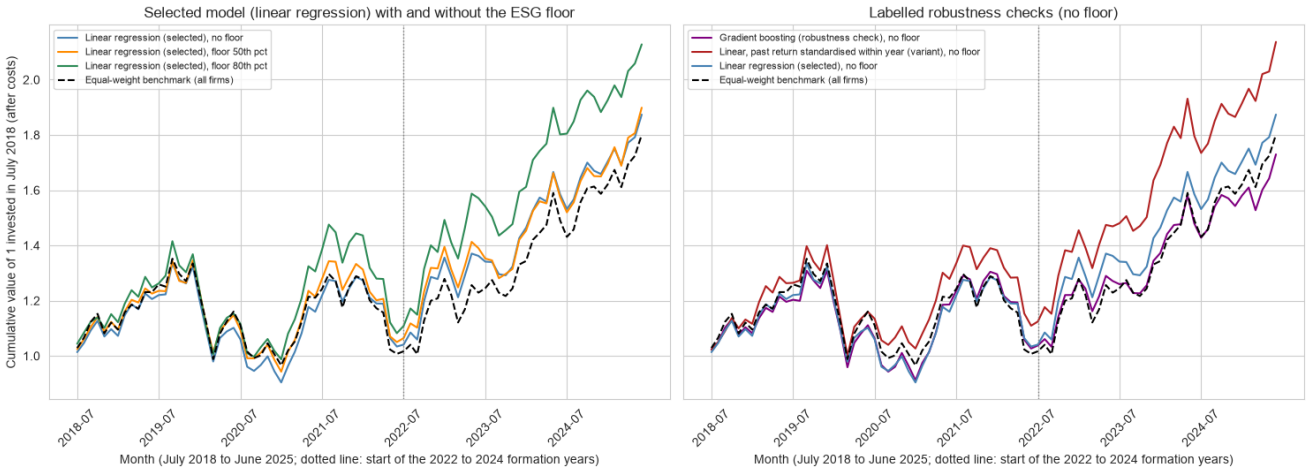

Figure d1 (notebook, (d) Step 4): cumulative value of 1 invested in July 2018 after costs. Left: the selected model with and without the floor against the benchmark. Right: the labelled robustness checks.

Only the clean out-of-sample years (formation 2022 to 2024, 36 months)	Return	Volatility	Sharpe
Linear regression, no floor	21.92	14.70	1.111
Linear regression, floor 50th	21.83	14.92	1.092
Linear regression, floor 80th	25.28	15.74	1.222

Only the clean out-of-sample years (formation 2022 to 2024, 36 months)	Return	Volatility	Sharpe
Equal-weight benchmark	21.37	15.17	1.052

Labelled robustness checks (not chosen on cross-validation)	Return	Volatility	Sharpe	Turnover
Gradient boosting, no floor	8.14	16.71	0.390	0.78
Gradient boosting, floor 50th / floor 80th	9.25 / 9.56	16.90 / 17.71	0.448 / 0.452	0.82 / 0.86
Linear, past return standardised within year, no floor	11.46	16.89	0.568	0.55
Same variant, floor 50th / floor 80th	10.83 / 10.24	16.92 / 18.08	0.534 / 0.481	0.60 / 0.69

3. What the numbers mean for an investor

- **No convincing edge.** The forecast has almost no ranking skill: the rank correlation between forecast and realised return averages +0.01 over 2018 to 2024 (+0.03 in 2018 to 2021, -0.02 in 2022 to 2024, and it changes sign across years). The strategy holds about 94 names against about 945 for the benchmark, so a gap of 0.6 points a year is what a different, equally unskilled selection of names could produce.
- **What the floor costs.** Not return in this sample. The 50th-percentile floor earned +0.2 points against no floor and the 80th +2.0 points. What it cost: fewer names (47 and 19 instead of 94), more volatility (17.1% and 18.4% against 16.8%) and more trading (turnover 0.76 and 0.82 against 0.70, a cost drag of 0.31 and 0.33 points a year against 0.28). The 80th-percentile result rests on about 19 names a year, so it should not be read as an ESG effect: the forecast has no skill and, in task (c), only Europe from 2021 shows a relation between the score and returns.
- **Is the difference to the benchmark noise?** Yes, for all three rules the interval contains zero. The best rule's Sharpe difference is +0.11 (interval -0.16 to +0.38). Three cautions: picking the best of three rules after seeing the results flatters it; months are resampled independently although returns can be autocorrelated; 84 months are few.
- **The clean out-of-sample years** (July 2022 to June 2025, a strong market) tell the same story: 21.9% against 21.4% without a floor; the Sharpe ratios 1.11 and 1.05 are close.
- **Robustness.** Gradient boosting earned 8.1% without a floor (below the benchmark). A linear variant with the past return standardised within year earned 11.5% (Sharpe 0.57), the highest no-floor result, but it was not the model selected in task (b), and choosing it now because it looks best would be selecting on the test period.

4. Suggested text (edit freely)

Memo (about 130 words). Each 1 July we ranked firms on the forecast of the model selected in (b) (linear regression, refitted each year on earlier formation years only), held the top decile for twelve months and charged 20 bp per unit of one-way turnover, on the full panel including firms that left (formation years 2018 to 2024). The rule earned 9.4% a year against 8.8% for the equal-weight benchmark (Sharpe 0.46 against 0.42). Restricting the pool to firms at or above the 50th and 80th percentile of the Environmental score gave 9.6% and 11.4%, so the floor did not cost return here; it cost concentration (about 19 names at the 80th percentile) and trading. The best rule's Sharpe advantage (+0.11) is not distinguishable from noise: the 95% interval is -0.16 to +0.38 (84 months resampled).

Slide (backtest with the floor, about 1.5 minutes). Title: "A backtest with an ESG floor: no edge that beats noise". Figure d1 (left) or the four-row table. One line: "Sharpe difference to the benchmark +0.11, interval -0.16 to +0.38; floor cost concentration, not return".

5. Plain-language guide: what the notebook did

- **Step 1, forecasts.** For every formation year from 2018 to 2024 the model is trained only on earlier years (for 2018: 2015 to 2017) and forecasts the return of every firm for the next year. A real investor never has later data, so neither do we.
- **Step 2, portfolios and costs.** Each July: take the firms of the pool, pick the 10% with the highest forecast, hold them equally weighted until the next June (firms that leave contribute until their last month), and charge trading costs on the share of the portfolio that changed. The floor versions first remove firms with a low Environmental score. The benchmark holds all firms equally.

- **Step 3, bootstrap.** Resample the 84 months with replacement 5,000 times and recompute the Sharpe difference each time, to see how much it moves by chance. The interval is the middle 95% of these differences.
- **Step 4, figure** of the cumulative return series.
- **Step 5, numbers for results.json** (four rules and the bootstrap).
- **Final cell.** Collects everything from tasks (a) to (d), checks that no number is missing or infinite, and writes results.json with the group name Group_8 and the three members.

6. Questions you may be asked

Question	Answer
Why does the strategy beat the benchmark if the forecast has no skill?	It does not beat it in any way that can be told from chance: the interval of the Sharpe difference contains zero. The 0.6-point gap comes with a very different portfolio (94 names against 945).
Why did the floor not cost return?	With 19 to 47 names the result is dominated by which names happen to be picked. We make no claim that ESG screening adds return. The honest cost of the floor is concentration and trading.
Why start in 2018?	The first forecast needs several earlier years to train on (2015 to 2017). Formation 2025 has only 6 months of returns and is left out.
Is the benchmark fair?	It is equal weight on all firms of the formation panel including firms that left, with no cost, as in the starter. Using survivors only would raise it by about 0.6 points a year (audit).
How realistic are the costs?	A flat 20 bp each way is a simplification. Real costs vary by stock size and market conditions; the memo should say so.
Why bootstrap months?	To see how much the Sharpe difference moves by chance with only 84 months. Independent resampling ignores autocorrelation, so the interval may be somewhat too narrow.

7. What to be careful about

- Do not present the 80th-percentile floor (11.4%) as an ESG result: 19 names, no forecast skill, interval contains zero.
- Do not pick the linear variant because it looks best: it is a labelled robustness check.
- The tuning of gradient boosting was done once on the training years of task (b), a simplification stated in the notebook.
- Report the benchmark next to every metric. Say that the sample is 84 months in one mostly rising market.
- Numbers come from one run on 3 November.
